## NOTICES

When Government drawings, specifications, or other data are used for any purpose other than in connection with a definitely related Government procurement operation, the United States Government thereby incurs no responsibility nor any obligation whatsoever; and the fact that the Government may have formulated, furnished, or in any way supplied the said drawings, specifications, or other data, is not to be regarded by implication or otherwise as in any manner licensing the holder or any other person or corporation, or conveying any rights or permission to manufacture, use, or sell any patented invention that may in any way be related thereto.

Qualified requesters may obtain copies of this report from the Armed Services Technical Information Agency, (ASTIA), Arlington Hall Station, Arlington 12, Virginia.

This report has been released to the Office of Technical Services, U.S. Department of Commerce, Washington 25, D.C., in stock quantities for sale to the general public.

Copies of this report should not be returned to the Aeronautical Systems Division unless return is required by security considerations, contractual obligations, or notice on a specific document.

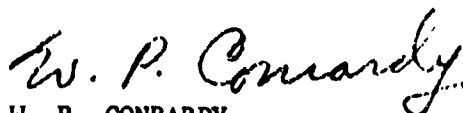

## ABSTRACT

A program was conducted to obtain detailed tensile, stress rupture and fatigue data on a series of high-strength steels. Data were obtained from D6AC, LaBelle HT, Thermold J, Vascojet 1000 and Peerless 56, heat treated to nominal ultimate strength of 280,000 psi.

Tests were conducted at room temperature and at elevated temperatures, the particular temperatures being selected according to the material. Maximum test temperature was 1000°F.

Dynamic creep data were obtained in conjunction with the fatigue tests.

This technical documentary report has been reviewed and is approved.

## I. INTRODUCTION

The designer of airborne systems is continually faced with the necessity of selecting the best materials and obtaining the maximum load-carrying efficiency from them. As these systems become more sophisticated, the designer is subjected to ever-increasing pressure to refine his procedures and to utilize the materials to higher proportions of their potential strength. Implicit in this process is an improved knowledge of the behavior of these materials and more specific information regarding their mechanical properties.

In the early history of airborne equipment, structures were designed with the intent that they not yield or fracture under conditions of maximum load. Since the knowledge of yield strength or ultimate strength of the materials used was rather meager, large safety factors were necessary if any degree of reliability was to be achieved. This, of course, led to inordinately heavy structures with consequently low cargo carrying capacity. Over the years the design process was refined and more detailed knowledge of tensile properties of the materials was gained, with the result that some degree of efficiency was attained even though the basis was essentially the same as originally. The use of these materials was pushed toward the region of higher stress levels, and consequently reduced safety factors, until these materials began to operate in a regime wherein failure by fatigue became important if not predominant. Thus, the aircraft industry became vitally interested in the subject of fatigue and in the fatigue properties of materials.

Further in the development of aircraft came an increase in temperatures, particularly with the advent of the turbine engine. This revealed another type of failure which resulted from steady loads applied for a long time at high temperatures. This type of failure is characterized by a gradual increase in dimension (creep) which, if sufficient time is involved, culminates in fracture (stress rupture). Either of these features may be serious, that of the stress rupture being obvious, and that of the creep being serious in cases wherein small changes in dimension are not permissible. As a result, many theoretical studies of fatigue, creep, stress rupture, and many tests, both on laboratory specimens and on structural components, have been conducted in order to establish acceptable design levels of loading under these conditions.

More recently, the designer has been faced with the problem of utilizing materials under combinations of the above conditions. Many cases exist in which a part is subjected to steady load at high temperature but with superimposed alternating loads. Ratios of alternating load to steady load can range from one extreme to the other. Only a few experimental studies have been made of this subject. Thus, there is a shortage of knowledge as to any possible interactions between these two types of loading wherein fatigue, creep, or stress rupture failures might be expected to occur.

---

Manuscript released by the author, March 1962, for publication as an ASD Technical Documentary Report.

The project being reported here was designed to provide information on the behavior of a group of high-strength steels under various combinations of alternating stress, mean stress, and temperature. Tests were conducted on five steels having nominal ultimate strengths of 280,000 psi.

Tests were conducted at stress ratios (stress ratio (A) =  $\frac{\text{alternating stress}}{\text{mean stress}}$ ) of 0, 1, and  $\infty$ , with test temperatures ranging from room temperature to 1,000°F. Both notched and unnotched specimens were tested. Measurements of elongation versus time were made in all cases wherein cyclic stresses were present and in some cases wherein only steady stresses were present (stress rupture tests). In addition, simple tensile test data were obtained.

Detailed test data from all tests are presented in the Appendix. Other portions of the report, particularly the Results and Discussion Sections, summarize the results and indicate relationships of material response to the test variables.

## II. SPECIMENS

Details of the sources and compositions of the five alloys involved in the test program are given in Table 1.

Heat treatment information is given in the tables of fatigue data, Tables 5 through 9 of the Appendix.

TABLE 1  
TEST MATERIALS

Alloy	Supplier	Heat No.	C	Mn	Si	S	P	Cr	V	Ni	Mo
D6AC	Crucible	S9706	.44	.64	.24	.010	.006	1.03	.06	.50	1.01
LaBelle HT	Crucible	53428	.42	1.35	2.25	.015	.015	1.30	.27		.39
Thermold J	Universal-Cyclops	D21144	.48	.41	1.09	.007	.017	4.96	1.01	1.55	1.49
Vascojet 1000	Vanadium Alloys	31658	.40	.27	.88	.010	.016	4.97	.50		1.30
Peerless 56	Crucible	44526	.40	.58	1.07	.017	.015	3.21	.32		2.50

Heat treating procedures intended to produce 280,000 psi ultimate strength were obtained from the literature and from the respective suppliers

of the materials. Details of these procedures are given at the head of each table of data in the Appendix. Detailed tensile test data at the various temperatures are also to be found in the Appendix. Average values of room temperature tensile data for the unnotched specimens are, however, given in Table 2.

TABLE 2  
AVERAGE ROOM TEMPERATURE TENSILE DATA (UNNOTCHED)

Material	0.2% Y.S.	U.T.S.	% Elongation	% R.A.
D6AC	237,000	270,000	5.3	38.3
LaBelle HT	237,000	291,000	7.6	40.5
Thermold J	275,000	338,000	5.7	25.4
Vascojet 1000	251,000	309,000	7.1	36.0
Peerless 56	252,000	297,000	5.5	27.2

As indicated in Table 2, ultimate strengths generally ranged somewhat above the intended value of 280,000 psi. This is particularly the case with Thermold J, for which the relation between ultimate strength and tempering temperature is quite steep in this range.

Microphotographs of each of the materials are shown in Figures 1 through 5.

Materials were purchased in the annealed condition in the form of one-half inch bar. Specimens were machined to the configurations shown in Figures 6-7. Notches are calculated to give a theoretical stress concentration of 3.0. The machining procedure consisted of rough machining to approximately .030-inch oversize, after which the specimens were heat treated. Following the heat treatment, specimens were ground to finish dimensions using a series of grinding passes of decreasing depth. Unnotched test sections were longitudinally machine-polished with a 600-grit belt. Notch root radii were polished by means of a rotating abrasive thread.

### III. TEST EQUIPMENT

Fatigue tests were conducted on a Type PVQ Schenck vertical fatigue machine of six-ton capacity. The machine is shown in Figure 8. This machine was purchased new shortly before the initiation of the present testing program. It is a special machine in that the requirements for specimen alignment were held to closer tolerances than normal. The control system of

FIGURE 7 TENSILE & STRESS RUPTURE SPECIMENS

Figure 8. Schenck Fatigue Machine

this fatigue machine is such that both mean load and alternating load are automatically maintained constant during the life of the specimen. The machine operated at approximately 3100 cps during the test program, the exact speed being dependent upon the particular load being applied. A Siemens's three-zone furnace and controller were used in conjunction with the Schenck machine for the elevated temperature tests. The furnace and controller were calibrated using a hollow dummy specimen equipped with thermocouples. After initial proportioning of the three zones, longitudinal temperature distribution was held within  $\pm 3^{\circ}\text{F}$ . Average temperature was also held within  $\pm 3^{\circ}\text{F}$ .

The specimen grips and pull rod extensions are shown in Figure 9. The specimen is threaded into the pull rods and secured with lock nuts. The pull rods are attached to the load-carrying members of the machine by means of the usual pinned split-washer and lock nut arrangement, which permits torque-free specimen installation.

Figure 9 also shows the mechanism used for measurement of elongation during fatigue testing. This arrangement consists of a linear variable differential transformer activated by relative motion of the specimen grips. The output signal is amplified, rectified, and fed to a Rustrak recorder. Sensitivity was adjusted so that one centimeter on the recorder paper corresponded to .001 inch of elongation. The recorder paper was divided into divisions corresponding to .0002 inch, thus enabling a resolution of better than .0001 inch.

The Schenck machine normally utilizes the change in specimen stiffness, as a crack develops, to activate the shut-off mechanism. With the high-strength steel specimens, cracks developed so rapidly that the machine usually did not shut off for some period of time after the specimen had fractured, thus resulting in damage to the fracture surfaces. An accelerometer switch was attached to the lower grip and used to remove the driving power and to activate a braking system. This stopped the machine within a few seconds after specimen fracture.

The tensile and stress rupture tests were conducted by New England Materials Laboratory, Medford, Massachusetts. Tensile tests were conducted on a 60,000-pound Baldwin Universal testing machine equipped with an alundum-tube resistance furnace and Honeywell controller. Stress rupture tests were conducted on machines of New England Materials Laboratory design. These machines are also equipped with alundum tube resistance furnaces and Honeywell controllers in both machines. Temperatures were held to a maximum of  $\pm 3^{\circ}\text{F}$ . Although creep data were not a required aspect of the program, these data were taken on a number of specimens. The elongation during testing was measured by means of dial indicators activated by rods clamped to the specimen grips. Final elongation measurements were made on a pre-determined gage length.

Figure 9. Mounting of Fatigue Specimen  
and Extensometer

#### IV. TEST SCHEDULE

An outline of the test program is given in Table 3. It will be noticed that tensile and fatigue tests were conducted at room temperature and at two elevated temperatures. Room-temperature stress-rupture tests, however, appeared impractical. Thus, these tests were conducted only at elevated temperatures. In the cases of the high-chromium die steels (Thermold J, Vascojet 1000, and Peerless 56) wherein usable strengths remain at 1000°F, tests were conducted at three elevated temperatures. Two elevated temperatures were selected for each of the other two materials.

As previously noted, specimen elongation was measured during the fatigue tests and a portion of the stress-rupture tests.

The stress-rupture loads were selected to allow interpolation to a rupture life of 55 hours. This time corresponds to that required for the accumulation of 10 million cycles by the Schenk fatigue machine. Thus, comparison of fatigue and creep stress levels and elongations can be made at corresponding lengths of life.

#### V. RESULTS

All detailed test data, except creep versus time data, are tabulated in the Appendix. The dynamic creep data were taken as continuous chart recordings and, hence, are not represented as discrete points. These data are, therefore, given as plots of elongation versus time. It will be noted that only a small number of fatigue specimens are represented on these plots. Most specimens did not show significant elongation and are thus considered as having exhibited no creep. This group consisted predominantly of specimens tested at room temperature, those tested under conditions of zero mean load and those which were notched. Static creep data are also presented as plots.

Modified Goodman Diagrams are presented in Figures 10 through 14. Fatigue data in these diagrams are taken as the values of stress at which a specimen would be expected to have a life of 10 million cycles. Under the test conditions, approximately 55 hours were required to accumulate this number of cycles. Thus, the rupture strengths at 55 hours were used for the corresponding points on the horizontal axes. These points were obtained by interpolation of the rupture diagrams, Figures 51 through 55.

## VI. DISCUSSION

### A. Fatigue Characteristics

Examination of the modified Goodman Diagrams (Figures 10 through 14) shows that, for the most part, mean stress and temperature cause a decrease in the allowable alternating stress, as would be expected. Because of the limited number of stress ratios available, it is not possible to draw accurate curves of these effects. Thus, the test points are joined by straight lines.

The most notable unusual result is seen in the case of the Vascojet 1000 at room temperature. A marked drop in alternating stress to failure was observed at a stress ratio of 1.0 for the unnotched case. This point is, in fact, lower than the corresponding point for notched specimens. This can also be noted in the S-N Diagram, Figure 39, in the long-life region. A careful review of the test procedure was made on the suspicion of experimental error. No errors were found. Further, hardness checks and metallurgical examination indicate that the heat treatment was correct. There is a slight qualitative indication of hydrogen embrittlement. This is not apparent, however, in the tensile or stress-rupture data and, therefore, would have to be confined to the specimens used for the particular S-N Diagram. In any case, it is apparent that some unknown factor exists regarding this point on the Goodman Diagram and that the point should not be weighted heavily.

Figure 15 shows the appearance of the failed surfaces of this group of specimens. It can be seen that the failures started at or near the surface. This might suggest the possibility of bending loads in the machine. These particular tests were intermingled with others, however, which exhibited normal fatigue strengths. Figure 16 shows specimens from another test in which the failures were predominantly of subsurface origin, indicating good machine alignment.

Figure 17 is a plot of the fatigue limits as ratios of ultimate strengths for the parent materials at a stress ratio of infinity. The ratios hold reasonably constant with temperature and have values normally to be expected for very high strength steels.

Table 4 lists values of strength reduction factor,  $K_f$ , for the various materials. Values of notch sensitivity,  $q$ , are also tabulated. In this case "q" is based on a biaxial stress factor ( $K_{T1}$ ) of 2.7, where the uniaxial factor ( $K_T$ ) for the notches is 3.0. These values are determined from curves in Reference 1. Again, it can be seen that the Vascojet exhibited some rather unusual behavior.

## B. Stress Rupture Characteristics

Examination of the stress rupture plots, Figures 51 through 55, shows that the stress versus time function is very flat except for those tests conducted at 1000°F and the test of Peerless 56 at 800°F. As previously noted, the values for  $A = 0$ , as used in the Goodman Diagrams, were taken from these data, using a life of 55 hours. In cases wherein all data were at shorter times, the curves were extrapolated to 55 hours.

Examination of the failed surfaces of the stress rupture specimens revealed no consistent pattern. There was some tendency, at the higher temperatures, for the fractures to tend from transcrystalline to intercrystalline as the time to rupture increased.

Figures 18 and 19 show the elongation at fracture for failed specimens at the higher temperatures for each material. Although there is considerable variation in elongation at nearly constant stress, there is a definite trend, particularly at the highest temperatures, for final elongation to increase with stress level.

## C. Creep

As previously mentioned, static creep versus time data were obtained on some of the stress rupture specimens and all of the fatigue specimens. The static data are given in Figures 56 through 67. The significant dynamic creep data are given in Figures 68 through 73. The difference in vertical scale between these two groups of figures should be noted. It can be seen that final elongation of the stress rupture specimens is about an order of magnitude greater than that of the fatigue specimens shown.

The static and dynamic creep data were examined rather thoroughly in an effort to arrive at a correlation with respect to the significant parameters, i.e. maximum stress, stress ratio, time and temperature. In particular, the data were examined to establish what effect, if any, the dynamic stress might have on creep behavior. Primarily because of the lack of experimental reference between the creep data and the fatigue data (i. e. the large difference in stress ratios or maximum stresses), correlation of the many factors is quite limited. It becomes apparent that, at the stress ratios involved, the predominant mode of failure in the dynamic tests was that of fatigue with very little elongation. The static tests were characterized generally by much greater elongations. There appears to be very little interaction between the two modes of failure under the conditions of test. Because of the nonlinear behavior of creep versus time in general, it is deemed hazardous to interpolate between the two extremes of fatigue and stress rupture loading condition. This is further pointed out by Lazan (Ref. 2, 3) who notes that theoretical expressions are available but that, because of the associated assumptions, they must be used with extreme caution if serious errors are to be avoided.

FIGURE 18 FINAL ELONGATION OF STRESS RUPTURE SPECIMENS

FIGURE 19 FINAL ELONGATION OF STRESS RUPTURE SPECIMENS (CONTINUED)

Theory and experiment do not compare well. It thus remains necessary to resort to experiment if knowledge of the interaction of static and dynamic loads on creep behavior of specific materials is to be obtained. This is particularly true in the area where interaction is greatest; at stress ratios (A) between zero and one.

Examination of the dynamic creep data indicates that significant creep occurred only under the combination of elevated temperature and pressure of mean stress ( $A = 1$ ) in the unnotched specimens. Several parameters were plotted in an effort to depict this effect. The only one which resulted in a reasonable plot without excessive scatter was that of the product of stress and time. It is realized, of course, that under the conditions of test, these variables are not completely independent. Figure 20 gives the result of the use of the stress-time parameter and shows the effect of mean stress on total dynamic creep at fracture for unnotched specimens. Only tests of unnotched specimens at 1000°F are shown and only those specimens which showed creep other than zero are plotted.

It is not possible to conclude from the data in Figure 20 that the dynamic stress has an effect on creep. Static data plotted in this same manner would yield very much higher values of elongation for the same value of the stress-time parameter. This might be expected as a result of the greatly different stress levels between the two types of test. Thus, the only positive conclusion can be that the mean stress in the fatigue tests at high temperature and a stress ratio of 1.0 is sufficient to cause a small amount of creep. No conclusions regarding the effect of the dynamic load can be drawn. In other words, no data on static creep at stress levels corresponding to those in the dynamic tests are available for comparison.

#### D. General Comments

The following additional general observations were made, particularly with regard to the appearance of the fatigue fractures:

1. Microscopic examination of the failed surfaces of the groups of specimens which exhibited unusual fatigue behavior did not reveal any apparent differences in mode of fracture as compared to those displaying normal behavior. This comment applies particularly to the LaBelle HT at 450°F and the Vascojet at 75°F and 800°F.

2. Fatigue curves were examined with respect to the presence of inclusions and the size of inclusions at which fatigue failure nucleated. Although a number of spherical inclusions as large as 0.003-0.004 inch diameter were observed, their presence and size did not correlate with fatigue strengths of the individual specimens.

FIGURE 20 EFFECT OF MEAN STRESS ON CREEP UNDER FATIGUE LOADING

3. The fractured surfaces of the high-temperature fatigue specimens exhibited a greater degree of shear failure than did those at the lower temperatures. As a result, the high-temperature failures are quite jagged in appearance. The low-temperature specimens all exhibited some degree of shear failure. This is fairly constant in degree at all stress levels and tends to be uniformly distributed around the circumference.

4. At the higher temperatures a number of specimens exhibited a fluted formation in the fatigue area. At lower temperatures there is a suggestion of the same mechanism, but it never becomes fully developed.

## VII. CONCLUSIONS

1. Extensive data were obtained on the tensile, stress rupture and fatigue properties of five high-strength steels at room and elevated temperatures in both the unnotched and the notched conditions. Dynamic creep data were obtained in connection with the fatigue tests.

2. Dynamic creep was shown to be very small under most conditions of test. Creep of significant degree occurred only under conditions of maximum test temperature and maximum mean load ( $A = 1$ ) for the unnotched specimens. All other fatigue tests resulted in very small creep, generally within the limits of resolution of the extensometer. The maximum dynamic creep observed was 0.8%, this being confined to a single specimen.

3. Inasmuch as static creep data were not available at stress levels corresponding to those used in the fatigue tests, no conclusions can be reached regarding the influence of dynamic stress on creep.

4. The ratio of fatigue strength (at 10 million cycles) to ultimate tensile strength ranged from 0.23 to 0.37 for the unnotched materials at a stress ratio of  $A = \infty$ .

FATIGUE TEST DATA - PEERLESS 56

Heat No.: 44526

Heat Treatment: Heat to 1870°F in slightly reducing atmosphere. Hold 5 minutes. Air cool. Double temper 2 hours, plus 2 hours at 1050°F.

Aeronautical Systems Division, Dir/Materials and Processes, Applications Lab, Wright-Patterson AFB, Ohio.  
Rpt Nr ASD-TDR-62-480. FATIGUE AND DYNAMIC CREEP OF HIGH-STRENGTH STEELS. Summary report. Aug 62, 105pp incl illus., tables, 3 refs.

Unclassified Report

A program was conducted to obtain detailed tensile, stress rupture and fatigue data on a series of high-strength steels. Data were obtained from D6AC, LaBelle HT, Thermold J, Vascojet 1000 and Peerless 56, heat treated to nominal ultimate strength of 280,000 psi.

Tests were conducted at room temperature

( over )

and at elevated temperatures, the particular temperatures being selected according to the material. Maximum test temperature was 1000° F.

Dynamic creep data were obtained in conjunction with the fatigue tests.

1. Tensile fatigue
2. Rupture
3. Creep
- I. AFSC Project 7381, Task 738103
- II. Contract AF 33 (616)-6946
- III. Lessells and Associates, Inc. Boston, Mass.
- IV. R. F. Brodrick
- V. Secondary Rpt. Nr Proj. 681/c48
- VI. Aval fr OTS
- VII. In ASTIA collection

## FOREWORD

This report was prepared by Lessells and Associates, Inc. under United States Air Force Contract No. AF33(616)-6946. This contract was conducted under Project No. 7381, "Materials Application," Task No. 738103, "Data Collection and Correlation." The work was administered under the direction of the Applications Laboratory, Directorate of Materials and Processes, Aeronautical Systems Division, with Mr. V. Lardenoit acting as project engineer.

This report covers work conducted from January 1960 to March 1962.

Personnel at Lessells and Associates, Inc. who contributed to the program were E. T. Booth, R. F. Brodrick, B. P. Friesecke and B. H. Schofield. The project is identified internally as Project No. 681/c48.
